

The coupling-independent prediction. Linear lattice strain against inverse particle radius, one line per habit, exactly linear in $1/R$ because every quantity in the chain is. **No spin-strain coupling constant enters this figure**, so none of the 1.65x spread between the two published coupling sets applies to it -- unlike every MHz number in F5. The sign split is the signature: a -100° -dominated particle CONTRACTS while -110° - and -111° -dominated ones EXPAND, because (100) is the one surface with net tensile f . That direction is also independent of the absolute τ scale, so a size-resolved powder-XRD series identifies the dominant facet family from the sign of the shift alone and then tests the magnitude against the slope. $a_0 = 3.572997$ Å from config/reference'pbe'sssp.json. Epistemic level L1.
