

Surface energy against hydrogen chemical potential, which sets the range every later figure is quoted over. γ rises with $\Delta\mu_{\text{H}}$ at facet-dependent rates, so the stability ORDER changes and with it the equilibrium habit. The shaded band is where $\gamma \leq 0$ and a Wulff construction is undefined -- shown rather than hidden, because at the H-rich limit all three H-terminated facets sit there, which is why 'particle'strain.py --shape wulff' refuses. The dehydrogenation ceiling is NOT DRAWN: it requires a bare-facet ladder that is not in results/, so the hydrogen-poor side of this figure is unbounded and every statement made there is an extrapolation with no stop. That is the single largest limitation on this figure and on F3. Epistemic level L1: γ rests on a Boettger μ^{C} fit whose residual drift is recorded per facet in the config.
